# Path Planning

---

The planning problem has been studied extensively in various fields like robotics, artificial intelligence, and control theory. In this chapter, we discuss the fundamentals of path planning.

## 1.1 Preliminaries

### 1.1.1 Configuration Space

Each distinct situation of a world is called a *state*,  $x$ , and the set of all possible states is called a *state space*,  $X$ . The state,  $x$ , can be transformed to  $x'$ , by applying an *action*,  $u$ , as specified by a *state transition function*,  $f$ , such that:

$$x' = f(x, u) \quad (1.1)$$

The set of all possible actions for each state is defined as the *action space*,  $U(x)$ .

In path planning, we work with a special state space called the *configuration space*, or C-space. The configuration space,  $\mathcal{C}$ , of a robot is the set of all possible configurations,  $x$ , that could be achieved by it. The real beauty of C-space is in the way it deals with the obstacles. Suppose that the world,  $\mathcal{W}$ , contains an obstacle region,  $\mathcal{O}$ . Assuming that the robot,  $\mathcal{A} \subset \mathcal{W}$ , the *obstacle region*,  $\mathcal{C}_{obs} \subseteq \mathcal{C}$ , is defined as

$$\mathcal{C}_{obs} = \{x \in \mathcal{C} | \mathcal{A}(x) \cap \mathcal{O} \neq \emptyset\} \quad (1.2)$$

In other words,  $\mathcal{C}_{obs}$  is the set of all configurations at which the robot intersects the obstacle region. The *free space*, defined as,  $\mathcal{C}_{free} = \mathcal{C} \setminus \mathcal{C}_{obs}$ , is the set of all collision free configurations of the robot.

Let  $x_I \in \mathcal{C}_{free}$  and  $x_G \in \mathcal{C}_{free}$  be the *initial configuration* and the *final configuration* respectively. A path planning algorithm aims to compute a continuous path starting at  $x_I$  and ending at  $x_G$ .

### 1.1.2 Graph Search Algorithms

In this section, we cover the major graph search algorithms that will be useful in path planning. Forward search algorithms start at the initial state and explores the graph until encountering the goal state. The general template of such algorithms [1] is shown in Algorithm 1.

During the search, there will be three kinds of states. The *unvisited* list consists of all the unexplored states of graph. If a state, along with all its next possible states, have been visited, it is added to the *dead* list. The remaining states, i.e. the explored states with unexplored neighbours, forms the *alive* list. As shown in the Algorithm 1, the alive list is stored in a data structure  $Q$ . The main difference between the search algorithms is in the way they sort  $Q$ .

---

**Algorithm 1** Forward Search

---

```
1:  $Q$ .Insert( $x_I$ ) and mark  $x_I$  as visited
2: while  $Q$  not empty do
3:    $x \leftarrow Q$ .GetFirst()
4:   if  $x \in X_G$  then
5:     return SUCCESS
6:   for all  $u \in U(x)$  do
7:      $x' \leftarrow f(x, u)$ 
8:     if  $x'$  not visited then
9:       Mark  $x'$  as visited
10:       $Q$ .Insert( $x'$ )
11:   else
12:     Resolve duplicate  $x'$ 
13: return FAILURE
```

---

In *breadth first search*,  $Q$  is implemented as a First-In-First-Out (FIFO) queue. This results in a uniform expansion of the search frontier. If we make  $Q$  a stack, the graph would be explored aggressively in an arbitrary direction, resulting in the *depth first search*.

If we know the cost of the actions, we could use that to increase the efficiency of the search algorithm. In *Dijkstra's algorithm*,  $Q$  is sorted according to the *cost-to-come* function,  $C(x)$ , which is defined as the minimum cost of travelling from  $x_I$  to  $x$  according to the current knowledge.

In many cases, it is possible to obtain a heuristic estimate of the cost to reach the goal from any state. Let this function be called  $\hat{G}(x)$ . This knowledge can be exploited to reduce the number of states explored to reach the goal. The *A\* search algorithm* sorts  $Q$  according to the sum  $C(x) + \hat{G}x$ .

## 1.2 Basic Motion Planning Methods

### 1.2.1 Grid Based Search

In grid based search, the configuration space is discretized into grids. Each grid point represents a configuration, and the robot may move to an adjacent grid, as long as the line between them is contained in  $\mathcal{C}_{free}$ . This discretizes the set of actions, and hence the grid search algorithms can be applied to find the path from the start to the goal.

Grid based search works well for low dimensional problems. However, this method is computationally infeasible for high-dimensional systems, since the number of points on the grid increase exponentially with configuration space dimension.

### 1.2.2 Potential field based Search

In this method, the robot (represented in C-space), is treated as a particle under the influence of an artificial potential field. The potential field is designed in such a way that the goal has an *attractive potential* and the obstacles a *repulsive potential*. This ensures that the robot moves towards the goal while avoiding obstacles.

At every instance, the robot tries to move in a direction along decreasing potential. This method gives fast results in many cases, especially when the obstacles are stationary. However, this method will fail if the robot encounters a local minima.

### 1.2.3 Sampling-based Search

Sampling-based search algorithms are the leading methods to tackle higher-dimensional path planning problems. In this approach, the connectivity of  $\mathcal{C}_{free}$  is explored by sampling random configurations and trying to connect in a network. Here, configurations and actions are represented by nodes and edges respectively. Two major sampling-based methods: *rapidly-exploring random trees* (RRT) [1] and *probabilistic roadmaps* [2], are discussed in this section.

The RRT algorithm explores the space by randomly sampling a space-filling tree. As shown in Algorithm 2, the tree is rooted at the initial configuration, and with each new sample, a vertex is added between it and the nearest state in tree. Once we obtain a connected graph between the initial state and the goal, search algorithms can be used to compute the best path.

---

**Algorithm 2** Rapidly-exploring Random Trees

---

```
1:  $G.\text{init}(q_0)$ 
2: for  $i = 1$  to  $k$  do
3:    $q_{rand} \leftarrow \text{RAND\_CONFIG}()$ 
4:    $q_{near} \leftarrow \text{NEAREST\_VERTEX}(q_{rand}, G)$ 
5:    $q_{new} \leftarrow \text{NEW\_CONF}(q_{near}, q_{rand}, \Delta q)$ 
6:    $G.\text{add\_vertex}(q_{new})$ 
7:    $G.\text{add\_edge}(q_{near}, q_{new})$ 
8: return  $G$ 
```

---

Probabilistic roadmap is the preferred method if the initial and goal states are not fixed. This method consists of two stages: a preprocessing and query stages. In the preprocessing stage, a random configuration is generated, and neighbours within a predefined distance are connected. This step is repeated until a dense graph is generated. In the query stage, the start and goal configurations are connected to the graph, and an appropriate search algorithm is used to find the path.

## 1.3 Motion Planning for Quadrotors

This section is dedicated to motion planning methodologies for quadrotors. Our aim is to develop a planner that generates feasible path, that respects the input and dynamics constraints, to bring the quadrotor to the goal as soon as possible. To achieve this, we should exploit the internal dynamics of the quadrotor. Furthermore, it should find plans in real-time at rates around 50 Hz.

Until now, we assumed that the path between any two configurations can be easily determined. This is not always possible in the case of quadrotors, which have differential constraints that arise due to geometry and dynamics. *Kinodynamic motion planning* [3] methods can be used to approach such problems.

In general, there are two approaches to deal with this problem. In the first approach, the problem is solved by dividing it into global and local planning sub-problems. The global planner, typically implemented using sampling based search, computes a desired set of configurations through which the quadrotor moves while avoiding obstacles. Then the local planner generates time parametrized *trajectories* that can be realized by the vehicle. This method is simpler, but it may not lead to a global optimum as the geometric path is decided in advance, without considering the system dynamics.

The second approach relies on the differential flatness [4] property of the quadrotor dynamics to derive constraints on the trajectory and then solves an optimization problem to find

the optimum trajectory. Some interesting state-of-the-art path planning methodologies are discussed in this section.

### 1.3.1 Polynomial-Based Motion Planning

In [4], a methodology to generate a *minimum-snap trajectory*, that passes through the way-points while satisfying the constraints on velocity and acceleration, is developed. The trajectory is represented by piecewise polynomial functions and the trajectory generation function is formulated as a constrained quadratic programming problem.

In this method, the motor commands, and hence the accelerations, are proportional to the snap, or the fourth derivative, of path. Minimizing the snap gives rise to smooth trajectories that avoid paths involving extreme control inputs. Moreover, the resulting smoothness helps in maintaining the quality of onboard sensor measurements. Then, the segment times are optimized to minimize the total time.

The method presented in [5] jointly optimizes polynomial path segments in an unconstrained quadratic program to solve the minimum-snap trajectory problem. The output is numerically stable for high-order polynomials and large numbers of segments. They generated fast flight paths through cluttered environments by coupling this technique with an appropriate kinematic planner. Along with an implicit segment time allocation strategy, based on a single user-defined parameter on aggressiveness, they were able to generate far superior results.

### 1.3.2 Sampling-Based Motion Planning

### 1.3.3 Search-Based Motion Planning

## 1.4 Nonlinear Model Predictive Control

Model predictive control (MPC) refers to a set of controllers that use a model to compute inputs from the current time to a future time in order to optimise the behaviour of a model along the input trajectory. Since it is a computationally intensive algorithm, it was used in slow systems like chemical plants and oil refineries. Due to the recent increase in computational capabilities, MPC have become popular in robotics.

MPC is used to generate trajectories interpolating a given set of way-points [6] by calculating optimal controls online to minimize a cost function within a receding horizon. The constraints of the problem can be incorporated to the optimal control problem (OCP). In [7], a fast nonlinear model predictive control (NMPC) approach based on a geometric formulation of the error to track the MAV attitude on the  $SO(3)$  special orthogonal group.

Since the constrained optimization problem is computationally intensive, a trade-off has to be made between time horizon and policy lag. In [8], an unconstrained MPC problem is solved using Sequential Linear Quadratic (SLQ) solver, and trajectories of multiple seconds were generated within a few milliseconds. NMPC usually acts as a local planner for quadrotors. But this work combines trajectory optimization and trajectory control in a single approach.
